Regulation of Oxygen Homeostasis by Hypoxia-Inducible Factor 1

Metazoan organisms are dependent on a continuous supply of O2 for survival. Hypoxia-inducible factor 1 (HIF-1) is a transcription factor that regulates oxygen homeostasis and plays key roles in development, physiology, and disease. HIF-1 activity is induced in response to continuous hypoxia, intermittent hypoxia, growth factor stimulation, and Ca2+ signaling. HIF-1 mediates adaptive responses to hypoxia, including erythropoiesis, angiogenesis, and metabolic reprioritization. In each case, HIF-1 regulates the expression of multiple genes encoding key components of the response pathway. HIF-1 also mediates maladaptive responses to chronic continuous and intermittent hypoxia, which underlie the development of pulmonary and systemic hypertension, respectively.

The complexity of metazoan life is sustained by energy generated through oxidative metabolism of glucose and fatty acids in the mitochondria, which results in the production of reducing equivalents that are used to maintain an electrochemical gradient that drives ATP synthesis. This highly efficient mechanism for producing ATP is dependent on the utilization of O2 as the terminal electron acceptor at complex IV of the respiratory chain. When electrons react with O2 prematurely (e.g., at complex III), reactive oxygen species (ROS) are generated. Tonic, low-level ROS production represents a signal that mitochondrial function is intact, whereas increased ROS production, resulting from reduced or fluctuating O2 availability, is a danger signal that the cell is at risk of oxidative damage and, if uncorrected, death. Our understanding of the mechanisms by which cells and organisms sense hypoxia have dramatically advanced over the last two decades, principally through the discovery of hypoxia-inducible factor 1 (HIF-1) and the delineation of its role as a master regulator of oxygen homeostasis. This paper will provide an update on advances that have occurred in the field of oxygen biology since it was last reviewed in the inaugural issue of Physiology (78).

Oxygen Sensing and Signal Transduction

Increased or decreased O2 availability results in hyperoxia or hypoxia, respectively. Hypoxia occurs physiologically as a result of excessive (“overshock”) angio genesis (80) and clinically when O2 is delivered to patients at inappropriately high concentrations. Hypoxia is a fundamental physiological stimulus that occurs in response to tissue growth during normal development (11, 38, 80, 91, 92) and in disease states, such as anemia, hemorrhage, and pneumonia, that have afflicted humans and their ancestors throughout time and therefore have exerted selective pressure for the evolution of adaptive responses. In addition, modern man is afflicted by novel scourges associated with living long and/or unwisely, such as tobacco-related lung disease, atherosclerotic cardiovascular disease, and cancer, that have not exerted selective pressure due to their late onset, both with respect to reproduction of the individual and evolution of the species. Hypoxia can occur continuously or intermittently and be either acute or chronic in duration. Whereas chronic continuous hypoxia may occur either in a physiological or pathological context, chronic intermittent hypoxia only occurs in a pathological context. The distinction between physiological and pathological responses to hypoxia is important and will be delineated in greater detail below.

Continuous hypoxia

HIF-1 is a heterodimeric protein that is composed of a constitutively expressed HIF-1α subunit and an O2-regulated HIF-1β subunit (88). Under normoxic conditions, the HIF-1α subunit is synthesized and subjected to hydroxylase reaction on proline residue 402 and/or 564 by prolyl hydroxylase domain (PHD) proteins (principally PHD2) that use O2, and α-ketoglutarate as substrates (FIGURE 1A) to catalyze a dioxygenase reaction in which one oxygen atom is inserted into the proline residue and the other oxygen atom is inserted into α-ketoglutarate to form succinate and CO2 (12, 30). The protein OS-9 binds to both PHD2 and HIF-1α, thereby facilitating hydroxylation (4). Prolyl hydroxylation is required for the binding of the von Hippel-Lindau protein (VHL), which interacts with Elongin C and thereby recruits a ubiquitin ligase complex (30, 31). The protein SSX2, which interacts with HIF-1α, VHL, and Elongin C, stabilizes the interaction of VHL with Elongin C, thereby facilitating ubiquitination of HIF-1α (2). Ubiquitination marks
HIF-1α for degradation by the proteasome (68). FIH-1 binds to HIF-1α and negatively regulates transactivation function (49) by hydroxylating asparagine residue 803, which blocks the interaction of the HIF-1α transactivation domain with the co-activator p300 or CBP (41). Thus both the stability and transcriptional activity of HIF-1 are negatively regulated by O2-dependent hydroxylation (FIGURE 1A).

When cells are acutely subjected to hypoxia, the hydroxylation reactions are inhibited as a result of substrate (O2) deprivation and/or increased mitochondrial production of ROS, which may inhibit the hydroxylases by oxidizing a ferrous ion in the catalytic site [24, 30]. The loss of hydroxylase activity increases HIF-1α stability and transactivation function, leading to its dimerization with HIF-1β, binding of HIF-1 to its recognition sequence 5’-(A/G)CGTG-3’ (71) in target genes, and increased transcription of target gene sequences into mRNA.

When cells are acutely subjected to hypoxia, the hydroxylation reactions are inhibited as a result of substrate (O2) deprivation and/or increased mitochondrial production of ROS, which may inhibit the hydroxylases by oxidizing a ferrous ion in the catalytic site [24, 30]. The loss of hydroxylase activity increases HIF-1α stability and transactivation function, leading to its dimerization with HIF-1β, binding of HIF-1 to its recognition sequence 5’-(A/G)CGTG-3’ (71) in target genes, and increased transcription of target gene sequences into mRNA.

1.5% O2 for 30 minutes induced and inhibited these cells, indicating a role for phospholipase mediated calcium-calcitonin gene-related peptide (CGRP) as a consequence of apneas triggered by the nasso-pharyngeal reflex (60). Of greater concern is the chronic intermittent hypoxia that occurs as a result of obstructive sleep apnea and causes cardiovascular disease (34), as will be discussed below. Despite the fact that intermittent hypoxia involves short (15–30 s) episodes of hypoxia followed by longer (e.g., 5 min) periods of reoxygenation, HIF-1 activity is induced, albeit by mechanisms that are distinct from those regulating its activity under conditions of chronic hypoxia (96). The signal transduction pathways by which intermittent hypoxia activates HIF-1 have been delineated in the PC12 rat pheochromocytoma cell line, in which hypoxia was previously shown to induce membrane depolarization and increased intracellular Ca2+ ([Ca2+]i). When these cells were exposed to 60 cycles of intermittent hypoxia, the hydroxylation reactions were inhibited as a result of substrate (O2) deprivation and/or increased mitochondrial production of ROS, which may inhibit the hydroxylases by oxidizing a ferrous ion in the catalytic site [24, 30]. The loss of hydroxylase activity increases HIF-1α stability and transactivation function, leading to its dimerization with HIF-1β, binding of HIF-1 to its recognition sequence 5’-(A/G)CGTG-3’ (71) in target genes, and increased transcription of target gene sequences into mRNA.
1.5% O2 for 30 s followed by 20% O2 for 5 min, HIF-1α protein and HIF-1α transcriptional activity were induced and increased further after 120 cycles (95). In these cells, intermittent hypoxia triggered NADPH oxidase-dependent ROS production, which induced phospholipase C activity, leading to the generation of inositol 1,4,5-trisphosphate (IP3) and diacylglycerol (FIGURE 1B). Binding of IP3 to its cognate receptor led to mobilization of intracellular Ca2+, which activated calcium-calmodulin kinase (CamK) and, together with diacylglycerol, induced protein kinase C (PKC) activity. PKC stimulated mTOR-dependent HIF-1α synthesis and inhibited PHD2-dependent degradation of HIF-1α (96). CamK phosphorylated the coactivator p300, thereby promoting its interaction with HIF-1α, leading to transcriptional activation (95). In contrast to continuous hypoxia, in which HIF-1α is rapidly degraded (1/2 < 5 min) on reoxygenation (88), HIF-1α levels remain persistently elevated following intermittent hypoxia due to the persistent activation of mTOR (96), a finding that has significance in the context of obstructive sleep apnea, in which pathological cardiovascular and respiratory responses persist for hours after the termination of intermittent hypoxia (63).

**Oxygen-Independent Mechanisms for Regulating HIF-1**

In addition to the O2-dependent pathways described above, O2-independent pathways regulating the synthesis and the degradation of HIF-1α have been delineated. These pathways appear to be particularly important in the context of cancer.

**Regulation of HIF-1α degradation**

Although the PHD2-VHL pathway is the critical mechanism regulating HIF-1α stability in response to changes in O2 concentration (FIGURE 1A), recent studies have revealed that the RACK1 protein can bind to HIF-1α and interact with Elongin C, thereby recruiting an E3 ubiquitin-protein ligase complex (46). RACK1 can substitute for VHL to promote ubiquitination and degradation of HIF-1α, leading to the inhibition of its transcriptional activity (95).

**FIGURE 2. Oxygen-independent regulation of HIF-1α protein levels**

A: The regulation of HIF-1α protein stability by RACK1 is shown. RACK1 binding is increased by treatment with the heat shock protein 90 (HSP90) inhibitor 17-allylamino-17-demethoxygeldanamycin (17-AAG) or by the calcium/calmodulin-dependent protein kinase (CamK) activator Ca2+. Binding of Ca2+ to calmodulin (Cam) activates calcium-calmodulin kinase (CaMK) and, together with diacylglycerol, induces protein kinase C (PKC) activity. PKC stimulates mTOR-dependent HIF-1α synthesis and inhibits PHD2-dependent degradation of HIF-1α (96). CamK phosphorylates the coactivator p300, thereby promoting its interaction with HIF-1α, leading to transcriptional activation (95). In contrast to continuous hypoxia, in which HIF-1α is rapidly degraded (1/2 < 5 min) on reoxygenation (88), HIF-1α levels remain persistently elevated following intermittent hypoxia due to the persistent activation of mTOR (96), a finding that has significance in the context of obstructive sleep apnea, in which pathological cardiovascular and respiratory responses persist for hours after the termination of intermittent hypoxia (63).

B: The regulation of HIF-1α protein synthesis by the PI3K-AKT-mTOR (purple) and MAP kinase (orange) pathways, which mediate phosphorylation of key regulators of translation (red), is shown. Arrow and blocked arrow indicate activation and inhibition, respectively.
degradation of HIF-1α (FIGURE 2A), with the critical distinction that RACK1-HIF-1α interaction is not O2-regulated. Although RACK1 was originally identified as a protein that stabilized interactions between PKC and its substrates, PKC activity is not required for RACK1-mediated ubiquitination and degradation of HIF-1α (46).

RACK1-mediated HIF-1α degradation has been demonstrated in two contexts. First, heat shock protein 90 (HSP90) is known to bind to HIF-1α, and HSP90 inhibitors have been shown to inhibit tumor growth and to induce protein degradation of HIF-1α even in cells lacking VHL (26). RACK1 was shown to compete with HSP90 for binding to the PAS-A subdomain of HIF-1α (46). Treatment with an HSP90 inhibitor such as 17-allylamino-17-demethoxygeldanamycin results in unopposed RACK1 binding leading to increased ubiquitination and degradation of HIF-1α. The ability of HSP90 inhibitors to induce HIF-1α degradation is dependent on RACK1 expression (46). These studies have delineated a novel mechanism of action contributing to the anti-cancer effects of HSP90 inhibitors.

RACK1 also appears to contribute to the mechanism of action of another important drug, cyclopamine, which is an immunosuppressant that prevents tissue rejection following transplantation by inhibiting calcineurin, a Ca2+/calmodulin-dependent serine/threonine protein phosphatase (44). Cyclopamine A has been shown to inhibit hypoxia-induced HIF-1α expression (14, 37). RACK1 consists of seven copies of the tryptophan-aspartate-rich WD40 repeat domain and forms dimers through homotypic interactions between the fourth WD40 (WD4) repeat domain (84). HIF-1α and Elongin C bind to the WD7 repeat domain on separate RACK1 monomers such that dimerization is required for RACK1 to recruit Elongin C to HIF-1α (47). Phosphorylation of RACK1 promotes its dimerization, and the catalytic subunit of calcineurin binds to RACK1 and mediates its dephosphorylation, thereby inhibiting dimerization and RACK1-dependent HIF-1α degradation (FIGURE 2A). Ionomycin, a calcium ionophore, was shown to increase HIF-1α levels even in RB1 cells, which lack functional VHL. (47) Thus calcineurin activation represents another mechanism, in addition to those identified in the response to intermittent hypoxia (FIGURE 1B), by which calcium signaling can increase HIF-1α activity (FIGURE 2A).

SSAT1, which shares 46% amino acid identity with SSAT2, also binds to HIF-1αs and promotes its ubiquitination and degradation (53). However, in contrast to SSAT2, which stabilizes the interaction of VHL and Elongin C (FIGURE 1A) and thereby promotes O2-dependent ubiquitination (22), SSAT1 acts by stabilizing the interaction of HIF-1α with RACK1 (FIGURE 2A). Thus the paralogs SSAT1 and SSAT2 play complementary roles in promoting O2-independent and O2-dependent degradation of HIF-1α, respectively.

Regulation of HIF-1α synthesis

The principal mechanism for transducing extracellular signals to the nucleus is by the binding of growth factors, cytokines, and other ligands to cognate receptors on the cell surface, leading to the activation of the phosphatidylinositol-3-kinase (PI3K) and MAP kinase pathways (FIGURE 2B). Signal transduction through these pathways stimulates cell survival, growth, and proliferation. An inevitable consequence of cell growth and proliferation is increased O2 consumption, so it is perhaps not surprising that these same signaling pathways induce what can be considered pre-emptive HIF-1 activity because it occurs in an O2-independent manner (19, 82, 86, 98).

Treatment of MCF-7 human breast cancer cells with heregulin, which binds to heterodimers composed of the human epidermal growth factor receptor family members HER2 and HER3, activates PI3K, which phosphorylates the serine-threonine kinase AKT (protein kinase B). Activated AKT phosphorylates and activates the mammalian target of rapamycin (mTOR), which regulates cell growth and proliferation. It is independent of mTOR activity (42). As in the case of HSP90 inhibitors (FIGURE 2A), rapamycin and its derivatives are a class of drugs currently in clinical trials as anti-cancer agents, and their anti-cancer effects are strongly associated with their inhibition of HIF-1α (50, 83).

HIF-1α-Mediated Adaptive Responses to Hypoxia

HIF-1α mediates cell autonomous, tissue-restricted, and systemic homeostatic responses to hypoxia. An illustrative example of each of these is described below.

Erythropoiesis

Red blood cells function to deliver O2 from the lungs to every cell in the body. Acute blood loss, ascent to high altitude, and pneumonia each results in a reduction in the blood O2 content. The ensuing tissue hypoxia induces HIF-1α activity in cells throughout the body, including specialized cells in the kidney that produce erythropoietin (EPO), a glycoprotein hormone that is secreted into the blood and binds to its cognate receptor on erythroid progenitor cells, thereby stimulating their survival and differentiation (29). Analysis of the sequences regulating hypoxia-induced EPO gene transcription. Subsequently, the erythropoietin induces proliferation of multipotential progenitor cells for the intestine, liver, and bone marrow. These cells then differentiate into red blood cells and hemoglobin expression is increased by coordinated transcription of the genes encoding the α and β chains of hemoglobin (66), transferrin and hepcidin (78, 96, 97).

Erythropoietin signaling is required to maintain normal tissue oxygenation, especially under conditions of acute hypoxia. Hypoxia-inducible factor-1α (HIF-1α) is a heterodimeric transcription factor composed of an α (HIF-1α) and a β (HIF-1β) subunit. HIF-1α is rapidly degraded in cells at normal oxygen concentrations, whereas HIF-1β is constitutively expressed. Hypoxia stabilizes HIF-1α, allowing it to bind to DNA and regulate target gene expression (80). HIF-1α targets include genes that are essential for oxygen delivery, such as erythropoietin, which drives the production of red blood cells, and genes involved in maintaining normal tissue oxygenation, such as prostaglandin E2 (PGE2), which is produced by the endothelium and helps maintain normal tissue oxygenation (103).

Adipecijonosis

Erythropoiesis is an example of a systemic hypoxic response that leads to the generation of new blood vessels in the local tissue environment. The hypoxic state in the local tissue environment activates HIF-1α expression and HIF-1α activity. The hypoxic state then coordinates the expression of multiple genes encoding angiogenic cytokines (FIGURE 3), including vascular endothelial growth factor (VEGF) and basic fibroblast growth factor (bFGF), which bind to cognate receptors on the cell surface, leading to the activation of the PI3K and MAP kinase pathways (FIGURE 2B). These pathways stimulate cell survival, growth, and proliferation, which is an inevitable consequence of cell growth and proliferation. An inevitable consequence of cell growth and proliferation is increased O2 consumption, so it is perhaps not surprising that these same signaling pathways induce what can be considered pre-emptive HIF-1 activity because it occurs in an O2-independent manner (19, 82, 86, 98).

An example of each of these is described below.

Erythropoiesis

Red blood cells function to deliver O2 from the lungs to every cell in the body. Acute blood loss, ascent to high altitude, and pneumonia each results in a reduction in the blood O2 content. The ensuing tissue hypoxia induces HIF-1α activity in cells throughout the body, including specialized cells in the kidney that produce erythropoietin (EPO), a glycoprotein hormone that is secreted into the blood and binds to its cognate receptor on erythroid progenitor cells, thereby stimulating their survival and differentiation (29). Analysis of the sequences regulating hypoxia-induced EPO gene transcription...
transcription led to the discovery of HIF-1 (72). Subsequently, HIF-1 has been shown to orchestrate erythropoiesis by coordinately regulating the expression of multiple genes encoding proteins responsible for the intestinal uptake, tissue recycling, and delivery of iron to the bone marrow for its use in the synthesis of hemoglobin (FIGURE 3A), including transferrin (66), transferrin receptor (48, 81), ceruloplasmin (53), and hepcidin (59). In addition, HIF-1 also activates transcription of the EPO receptor (51).

Erythropoiesis is impaired in Hif1a–/– (homozygous HIF-1α-null) embryos and the erythropoietic defects in HIF-1α-deficient erythroid colonies could not be corrected by cytokines, such as vascular endothelial growth factor (VEGF) or EPO, but were ameliorated by administration of Fe-salicylaldehyde isonicotinoylhydrazone, a compound that can deliver iron into cells independently of iron transport proteins, which was consistent with reduced levels of transferrin receptor in HIF-1α-deficient embryos and yolk sacs (93). In contrast, deficiency of HIF-2α (which, like HIF-1α, is O2 regulated, dimerizes with HIF-1β and activates target gene expression) has a major effect on EPO production in adult mice (23).

Angiogenesis

Erythropoiesis represents an adaptive response to systemic hypoxia. In contrast, angiogenesis represents a local tissue response to decreased oxygenation. As cells grow and proliferate, their consumption of O2 increases and HIF-1 activity is induced, either as a result of pre-emptive growth factor-mediated induction (FIGURE 2B) or as a result of tissue hypoxia (FIGURE 1A). HIF-1 then coordinately activates the transcription of multiple genes encoding angiogenic growth factors and cytokines (FIGURE 3B), including vascular endothelial growth factor (VEGF), stromal-derived factor 1 (SDF-1), placental growth factor (PLGF), angiopoietin 1 and 2, and platelet-derived growth factor B (5, 8, 18, 32, 76), which bind to cognate receptors on vascular endothelial and smooth muscle cells as well as on endothelial progenitor cells, mesenchymal stem cells, and other bone marrow-derived angiogenic cells (FIGURE 3B). In addition, HIF-1 regulates the expression of CXCR4 (79), which is the receptor for SDF-1, and VEGFR1 (22, 101).
Glucose and energy metabolism

Individual cells must adapt to O2 deprivation by reprogramming their metabolism. The metabolic alterations that are induced by hypoxia are profound (Figure 3C). Perhaps the most subtle adaptation identified thus far is a subunit switch that occurs in cytochrome c oxidase (COX; complex IV), in which the COX4-1 regulatory subunit is replaced by the COX4-2 isofrom as a result of HIF-1-mediated transcriptional activation of genes encoding COX4-2 and LON, a mitochondrial protease that is required for the hypoxia-induced degradation of COX4-1 (28). This subunit switch serves to optimize the efficiency with which COX transfers electrons to O2 under hypoxic conditions. Remarkably, the budding yeast Saccharomyces cerevisiae also switches COX subunits in response to hypoxia (40) but does so by a completely different molecular mechanism since yeast do not have a HIF-1 homolog. The similar regulation of COX activity in yeast and human cells indicates that the selection for O2-dependent homeostatic regulation of mitochondrial respiration is ancient and likely to be shared by all eukaryotic organisms (28).

A more drastic alteration is the shunting of pyruvate away from the mitochondria by the HIF-1-mediated activation of the PDK1 gene encoding pyruvate dehydrogenase (PDH) kinase 1 (55, 56), which phosphorylates the catalytic subunit of PDH, the enzyme that converts pyruvate into acetyl coenzyme A (AcCoA) for entry into the mitochondrial tricarboxylic acid cycle (Figure 3C), which generates reducing equivalents that are donated to the electron transport chain. The reduced delivery of substrate to the mitochondria for oxidative phosphorylation results in reduced ATP synthesis, which must be compensated for by increased glucose uptake via glucose transporters and increased conversion of glucose to lactate by the activity of glycolytic enzymes and lactate dehydrogenase-A (Figure 3C), which are all encoded by HIF-1 target genes (27, 67, 69, 71).

Induction of PDK1 expression will inhibit the oxidative metabolism of AcCoA derived from glucose but will not affect the oxidative metabolism of AcCoA derived from fatty acids. The most dramatic response to persistent hypoxia is the active destruction of mitochondria by selective mitochondrial autophagy (97).

Remarkably, mice embryos (27, 67), whereas null) embryos (27, 67, 45), which are heterozygous for a HIF-1α/HIF-1β knockout allele and are induced by hypoxia are profound (5). Increase of lung tissue from non-hypoxic mice, which are heterozygous for a HIF-1α/HIF-1β knockout allele and are induced by hypoxia are profound (5, 9, 45).

The following conclusions can be drawn regarding the adaptive significance of these metabolic responses to hypoxia were revealed by the finding that HIF-1α-deficient MEFs die when cultured under hypoxic conditions for 72 h but derive from dramatically increased ROS levels (35, 69). The cells can be rescued by overexpression of PDK1 or BNIP3, or by treatment with free-radical scavengers (35, 69). It has long been known that mitochondrial ROS production increases under hypoxic conditions (35, 69). Recent studies have demonstrated that acute hypoxia also leads to increased mitochondrial ROS production, which is required for the inhibition of HIF-1α hydroxylase activity (24). Exposure of wild-type (WT) MEFs to hypoxia for 48 h results in reduced ROS levels, in contrast to HIF-1α−/− MEFs in which ROS levels are markedly increased (35, 97).

The following conclusions can be drawn regarding the adaptive metabolic adaptation to hypoxia. The increase in glycolysis and decrease in respiration that occur in response to hypoxia do not represent a passive effect of substrate (O2) deprivation but instead represent an active response of the cell to counteract the reduced efficiency of respiration under hypoxic conditions, which in the absence of adaptation results in the accumulation of toxic levels of ROS. These studies indicate that a major role of HIF-1 is to establish, at any O2 concentration, the optimal balance between glycolytic and oxidative metabolism that maximizes ATP production without increasing ROS levels. Finally, analysis of lung tissue from non-hypoxic HIF-1α−/− mice, which are heterozygous for a HIF-1α-null allele and thus partially HIF-1α deficient, revealed an ~58% decrease in mitochondrial mass compared with WT littermates (97). This remarkable finding indicates that HIF-1 regulates mitochondrial metabolism even in the tissue exposed to the highest Po2, indicating that HIF-1 performs this critical function over the entire range of physiological Po2. Thus HIF-1 maintains the metabolic/redox homeostasis that is essential for metazoan cells to live with O2.
HIF-1-Mediated Pathological Responses to Hypoxia

Continuous hypoxia and pulmonary hypertension

The only organ to receive 100% of cardiac output is the lungs, which receive the blood that is pumped from the right ventricle. The pulmonary arterial circulation functions to load erythrocytes with O₂. Blood is then returned to the left heart from which it is pumped through the systemic circulation to all tissues of the body. In contrast to the pulmonary circulation, the systemic circulation dilates in response to hypoxia, which is an autoregulatory device to maintain tissue oxygenation. In contrast, arterioles in the pulmonary circulation constrict in response to hypoxia to shunt blood away from lung tissue that is not oxygenated. Whereas this is an adaptive response in the setting of pneumonia, it is maladaptive in the setting of chronic lung disease, in which alveolar hypoxia is widespread. The right ventricle is forced to pump against greater resistance (pulmonary hypertension), resulting in ventricular hypertrophy and ultimately heart failure. HIF-1 plays a key role in this maladaptive response as determined in a mouse model in which animals are maintained in an ambient tension, resulting in ventricular hypertrophy and augmented pulmonary vascular tone, and augmented pulmonary hypertension in response to chronic intermittent hypoxia (77). This phenotype is a striking complement to the impaired pulmonary vasconstrictive and cardiorespiratory responses to chronic hypoxia that are observed in Hif1a−/− mice (36, 94).

Chronic intermittent hypoxia and systemic hypertension

Whereas chronic continuous hypoxia induces pulmonary hypertension, chronic intermittent hypoxia (CIH) induces systemic hypertension. CIH occurs in individuals with obstructive sleep apnea (OSA), in which airway occlusion results in cessation of breathing leading to hypoxemia, which then arouses the individual to breathe. OSA may be a contributing factor in 30% of patients with essential hypertension (43). The carotid body is a small chemosensory organ located at the bifurcation of the internal and external carotid arteries that senses arterial Pao₂. CIH induces signaling from the carotid body that activates the sympathetic nervous system to load erythrocytes with O₂. Blood is then returned to the left heart from which it is pumped through the systemic circulation to all tissues of the body.

CIH induces systemic hypertension. CIH occurs in individuals with obstructive sleep apnea (OSA), in which airway occlusion results in cessation of breathing leading to hypoxemia, which then arouses the individual to breathe. CIH induces systemic hypertension. CIH occurs in individuals with obstructive sleep apnea (OSA), in which airway occlusion results in cessation of breathing leading to hypoxemia, which then arouses the individual to breathe. CIH induces systemic hypertension. CIH occurs in individuals with obstructive sleep apnea (OSA), in which airway occlusion results in cessation of breathing leading to hypoxemia, which then arouses the individual to breathe. CIH induces systemic hypertension. CIH occurs in individuals with obstructive sleep apnea (OSA), in which airway occlusion results in cessation of breathing leading to hypoxemia, which then arouses the individual to breathe.
pathetic nervous system, leading to increased catecholamine secretion, which increases arterial tone, leading to hypertension (43, 61). Exposure of HIF-1α−/− mice and their WT littermates to CIH for 10 days results in marked increases in systolic and diastolic blood pressures and a significant elevation in plasma norepinephrine concentration in the WT mice, where as their HIF-1α−/− littermates are unaffected (56). Remarkably, the carotid bodies of HIF-1α−/− mice, although structurally and histologically normal, do not respond to hypoxia, although they respond normally to CO and cyanide (36, 57).

CIH induces ROS production in rodents (62) and humans (16) and induces HIF-1α expression (58). Administration of the superoxide scavenger manganese tetraakis(1-methyl-4-phenyl)porphyrin pentachloride to WT mice blocks CIH-induced ROS production (57), hypertension (39), and HIF-1α induction (58). Remarkably, in HIF-1α−/− mice, there is a complete loss of CIH-induced HIF-1α expression and ROS production (58). These results indicate that ROS production is required for HIF-1α induction and that HIF-1α induction is required for ROS production, suggesting a feed-forward mechanism in which ROS induces HIF-1α, which induces more ROS, leading to higher HIF-1α expression (FIGURE 49).

In contrast to the physiological response to continuous hypoxia observed in MEFs described above, in which HIF-1α contributes to disease pathogenesis, in anemic hypoxia, which HIF-1α activity ameliorates increases in ROS levels (58). These results indicate that ROS production is required for HIF-1α induction and that HIF-1α induction is required for ROS production, suggesting a feed-forward mechanism in which ROS induces HIF-1α, which induces more ROS, leading to higher HIF-1α expression (FIGURE 49).

Summary and Perspective

This review has summarized a small sample of the tremendous progress that has been made recently in understanding the molecular physiology of oxygen homeostasis and how it is dysregulated in various disease processes. The interested reader is encouraged to consult the many recent reviews that discuss other aspects of hypoxia sensing machinery and its manipulation.

Adaptation to hypoxia is important in many circumstances that involve hypoxia. In the postischemic rat, hypoxia induction of HIF-1α in endothelial cells through HIF-1 induction of SDF-1 promotes homing and mobilization of EPCs (25). The use of HIF-1α is also critical in the recovery of perfusion after limb ischemia (26). Aging decreases endothelial progenitor cell recruitment through decreases in hypoxia-inducible factor-1α stabilization during ischemia (27). The aging process results in an increase in the activity of mTOR (28). This review has summarized a small sample of the tremendous progress that has been made recently in understanding the molecular physiology of oxygen homeostasis and how it is dysregulated in various disease processes. The interested reader is encouraged to consult the many recent reviews that discuss other aspects of hypoxia sensing machinery and its manipulation.
