Regulation of Oxygen Homeostasis by Hypoxia-Inducible Factor 1

Metazoan organisms are dependent on a continuous supply of O2 for survival. Hypoxia-inducible factor 1 (HIF-1) is a transcription factor that regulates oxygen homeostasis and plays key roles in development, physiology, and disease. HIF-1 activity is induced in response to continuous hypoxia, intermittent hypoxia, growth factor stimulation, and Ca2+ signaling. HIF-1 mediates adaptive responses to hypoxia, including erythropoiesis, angiogenesis, and metabolic reprogramming. In each case, HIF-1 regulates the expression of multiple genes encoding key components of the response pathway. HIF-1 also mediates maladaptive responses to chronic continuous and intermittent hypoxia, which underlie the development of pulmonary and systemic hypertension, respectively.

The complexity of metazoan life is sustained by energy generated through the oxidative metabolism of glucose and fatty acids in the mitochondria, which results in the production of reducing equivalents that are used to maintain an electrochemical gradient that drives ATP synthesis. This highly efficient mechanism for producing ATP is dependent on the utilization of O2 as the terminal electron acceptor at complex IV of the respiratory chain. When electrons react with O2 prematurely (e.g., at complex III), reactive oxygen species (ROS) are generated. Tonic, low-level ROS production represents a signal that mitochondrial function is intact, whereas increased ROS production, resulting from reduced or fluctuating O2 availability, is a danger signal that the cell is at risk of oxidative damage and, if uncorrected, death. Our understanding of the mechanisms by which cells and organisms sense hypoxia have dramatically advanced over the last two decades, principally through the discovery of hypoxia-inducible factor 1 (HIF-1) and the delineation of its role as a master regulator of oxygen homeostasis. This paper will provide an update on advances that have occurred in the field of oxygen biology since it was last reviewed in the inaugural issue of Physiology (70).

Oxygen Sensing and Signal Transduction

Increased or decreased O2 availability results in hyperoxia or hypoxia, respectively. Hypoxia occurs physiologically as a result of excessive (“overshoe”) angio genesis (80) and clinically when O2 is delivered to patients at inappropriately high concentrations. Hypoxia is a fundamental physiological stimulus that occurs in response to tissue growth during normal development (11, 38, 80, 91, 92) and in disease states, such as anemia, hemorrhage, and pneumonia, that have afflicted humans and their ancestors throughout time and therefore have exerted selective pressure for the evolution of adaptive responses. In addition, modern man is afflicted by novel scourges associated with living long and/or unwisely, such as tobacco-related lung disease, atherosclerotic cardiovascular disease, and cancer, that have not exerted selective pressure due to their late onset, both with respect to reproduction of the individual and evolution of the species. Hypoxia can occur continuously or intermittently and be either acute or chronic in duration. Whereas chronic continuous hypoxia may occur either in a physiological or pathological context, chronic intermittent hypoxia only occurs in a pathological context. The distinction between physiological and pathological responses to hypoxia is important and will be delineated in greater detail below.

Continuous hypoxia

HIF-1 is a heterodimeric protein that is composed of a constitutively expressed HIF-1α subunit and an O2-regulated HIF-1α subunit (88). Under normoxic conditions, the HIF-1α subunit is synthesized and subjected to hydroxylation on proline residue 402 and/or 564 by prolyl hydroxylase domain (PHD) proteins (principally PHD2) that use O2 and α-ketoglutarate as substrates (FIGURE 1A) to catalyze a dioxygenase reaction in which one oxygen atom is inserted into the proline residue and the other oxygen atom is inserted into α-ketoglutarate to form succinate and CO2 (12, 30). The protein OS-9 binds to both PHD2 and HIF-1α, thereby facilitating hydroxylation (4). Prolyl hydroxylation is required for the binding of the von Hippel-Lindau protein (VHL), which interacts with Elongin C and thereby recruits a ubiquitin ligase complex (30, 31). The protein SSA2, which interacts with HIF-1α, VHL, and Elongin C, stabilizes the interaction of VHL with Elongin C, thereby facilitating ubiquitination of HIF-1α (2). Ubiquitination marks
HIF-1α for degradation by the proteasome (68). HIF-1 binds to HIF-1α and negatively regulates transactivation function (49) by hydroxylating asparagine residue 803, which blocks the interaction of the HIF-1α transactivation domain with the co-activator p300 or CBP (41). This both the stability and transcriptional activity of HIF-1α are negatively regulated by O₂-dependent hydroxylation.

When cells are acutely subjected to hypoxia, the hydroxylation reactions are inhibited as a result of substrate (O₂) deprivation and/or increased mitochondrial production of ROS, which may inactivate the hydroxylases by oxidizing a ferrous ion in the catalytic site (24, 30). The loss of hydroxylase activity increases HIF-1α stability and transactivation function, leading to the dimerization with HIF-1β, binding of HIF-1 to its recognition sequence 5’-(A/G)CGTG-3’ (71) in target genes, and increased transcription of target gene sequences into mRNA. When cells are acutely subjected to hypoxia, the hydroxylation reactions are inhibited as a result of substrate (O₂) deprivation and/or increased mitochondrial production of ROS, which may inactivate the hydroxylases by oxidizing a ferrous ion in the catalytic site (24, 30). The loss of hydroxylase activity increases HIF-1α stability and transactivation function, leading to the dimerization with HIF-1β, binding of HIF-1 to its recognition sequence 5’-(A/G)CGTG-3’ (71) in target genes, and increased transcription of target gene sequences into mRNA.

**Intermittent hypoxia**

Brief episodes of hypoxia and reoxygenation (intermittent hypoxia) are known to occur during swimming as a consequence of apneas triggered by the naso-pharyngeal reflex (60). Of greater concern is the chronic intermittent hypoxia that occurs as a result of obstructive sleep apnea and causes cardiovascular disease (34), as will be discussed below. Despite the fact that intermittent hypoxia involves short (15–30 s) episodes of hypoxia followed by longer (e.g., 5 min) periods of reoxygenation, HIF-1 activity is induced, albeit by mechanisms that are distinct from those regulating its activity under conditions of chronic hypoxia (96).

The signal transduction pathways by which intermittent hypoxia activates HIF-1 have been delineated in the PC12 rat pheochromocytoma cell line, in which hypoxia was previously (13) shown to induce membrane depolarization and increased intracellular Ca²⁺ ([Ca²⁺]i). When these cells were exposed to 60 cycles of 1.5% O₂ for 30 s, HIF-1α protein and activity were induced and increased in these cells, indicating that O₂-dependent and -independent hydroxylation pathways differ in their responses to intermittent hypoxia (96). The finding that intermittent hypoxia activates HIF-1α in vitro without requiring the HIF-1α prolyl hydroxylase (PHD2) or asparaginyl hydroxylase (FIH-1) suggests that intermittent hypoxia may have distinct signaling pathways from chronic hypoxia.
1.5% O₂ for 30 s followed by 20% O₂ for 5 min, HIF-1α protein and HIF-1 transcriptional activity were induced and increased further after 120 cycles (95). In these cells, intermittent hypoxia triggered NADPH oxidase-dependent ROS production, which induced phospholipase C activity, leading to the generation of inositol 1,4,5-trisphosphate (IP3) and diacylglycerol (FIGURE 1B). Binding of IP3 to its cognate receptor led to mobilization of intracellular Ca²⁺, which activated calcium-calmodulin kinase (CamK) and, together with diacylglycerol, induced protein kinase C (PKC) activity. PKC stimulated mTOR-dependent HIF-1α synthesis and inhibited PHD2-dependent degradation of HIF-1α (96). CamK phosphorylated the coactivator p300, thereby promoting its interaction with HIF-1α, leading to transcriptional activation (95). In contrast to continuous hypoxia, in which HIF-1α is rapidly degraded (t₁/₂ < 5 min) on reoxygenation (88), HIF-1α levels remain persistently elevated following intermittent hypoxia due to the persistent activation of mTOR (96), a finding that has significance in the context of obstructive sleep apnea, in which pathological cardiovascular and respiratory responses persist for hours after the termination of intermittent hypoxia (63).

**Oxygen-Independent Mechanisms for Regulating HIF-1**

In addition to the O₂-dependent pathways described above, O₂-independent pathways regulating the synthesis and the degradation of HIF-1α have been delineated. These pathways appear to be particularly important in the context of cancer.

**Regulation of HIF-1α degradation**

Although the PHD2-VHL pathway is the critical mechanism regulating HIF-1α stability in response to changes in O₂ concentration (FIGURE 1A), recent studies have revealed that the RACK1 protein can bind to HIF-1α and interact with Elongin C, thereby recruiting an E3 ubiquitin-protein ligase complex (46). RACK1 can substitute for VHL to promote ubiquitination and degradation of HIF-1α.

**Oxygen-independent regulation of HIF-1α protein levels**

A: the regulation of HIF-1α protein stability by RACK1 is shown. RACK1 binding is increased by treatment with the heat shock protein 90 (HSP90) inhibitor 17-allylamino-17-demethoxygeldanamycin (17-AAG) or by the calcineurin inhibitor cyclosporine A (CsA). Binding of Ca²⁺ to calmodulin (Cam) activates calmodulin-dependent protein kinase (CamK) which inhibits RACK1 dimerization. B: the regulation of HIF-1α protein synthesis by the PI3K-AKT-mTOR (purple) and MAP kinase (orange) pathways, which mediate phosphorylation of key regulators of translation (red), is shown. Arrow and blocked arrow indicate activation and inhibition, respectively.
degradation of HIF-1α (FIGURE 2A), with the critical distinction that RACK1-HIF-1α interaction is not O₂-regulated. Although RACK1 was originally identified as a protein that stabilized interactions between PKC and its substrates, PKC activity is not required for RACK1-mediated ubiquitination and degradation of HIF-1α (46).

RACK1-mediated HIF-1α degradation has been demonstrated in two contexts. First, heat shock protein 90 (HSP90) is known to bind to HIF-1α, and HSP90 inhibitors have been shown to inhibit tumor growth and to induce proapoptotic degradation of HIF-1α even in cells lacking VHL (26). RACK1 was shown to compete with HSP90 for binding to the PAS-A subdomain of HIF-1α (46). Treatment with an HSP90 inhibitor such as 17-allylamino-17-demethoxygeldanamycin results in unopposed RACK1 binding leading to increased ubiquitination and degradation of HIF-1α. The ability of HSP90 inhibitors to induce HIF-1α degradation is dependent on RACK1 expression (46). These studies have delineated a novel mechanism of action contributing to the anti-cancer effects of HSP90 inhibitors.

RACK1 also appears to contribute to the mechanism of action of another important drug, cyclosporine A, which is an immunosuppressant that prevents tissue rejection following transplantation by inhibiting calcineurin, a Ca²⁺/calmodulin-dependent serine/threonine protein phosphatase (44). Cyclosporine A has been shown to inhibit hypoxia-induced HIF-1α expression (14, 37). RACK1 consists of seven copies of the cryptophane-aspartate-rich WD40 repeat domain and forms dimers through homotypic interactions between the fourth WD40 (WD4) repeat domain (84). HIF-1α and Elongin C bind to the WD7 repeat domain on separate RACK1 monomers such that dimerization is required for RACK1 to recruit Elongin C to HIF-1α (47). Phosphorylation of RACK1 promotes its dimerization, and the catalytic subunit of calcineurin binds to RACK1 and mediates its dephosphorylation, thereby inhibiting dimerization and RACK1-dependent HIF-1α degradation (FIGURE 2A). Ionomycin, a calcium ionophore, was shown to increase HIF-1α levels even in RCC4 cells, which lack functional VHL (47). Thus calcineurin activation represents another mechanism, in addition to those identified in the response to intermittent hypoxia (FIGURE 1B), by which calcium signaling can increase HIF-1α activity (FIGURE 2A).

SSAT1, which shares 46% amino acid identity with SSAT2, also binds to HIF-1α and promotes its ubiquitination and degradation (53). However, in contrast to SSAT2, which stabilizes the interaction of VHL and E elongin C (FIGURE 1A) and thereby promotes O₂-dependent ubiquitination (52), SSAT1 acts by stabilizing the interaction of HIF-1α with RACK1 (FIGURE 2A). Thus the paralogs SSAT1 and SSAT2 play complementary roles in promoting O₂-independent and O₂-dependent degradation of HIF-1α, respectively.

**Regulation of HIF-1α synthesis**

The principal mechanism for transducing extracellular signals to the nucleus is by the binding of growth factors, cytokines, and other ligands to cognate receptors on tyrosine kinases and G-protein-coupled receptors on the cell surface, leading to the activation of the phosphatidylinositol-3-kinase (PI3K) and MAP kinase pathways (FIGURE 2B). Signal transduction through these pathways stimulates cell survival, growth, and proliferation. An inevitable consequence of cell growth and proliferation is increased O₂ consumption, which in turn is thought to provide a selective growth advantage in hypoxic states (50). Thus the paralogs SSAT1 and SSAT2 play complementary roles in promoting O₂-independent and O₂-dependent degradation of HIF-1α, respectively.

**Erythropoiesis**

Erythropoiesis is a systemic process that leads to the production of red blood cells and HIF-1α activity is required to ensure erythroid growth, proliferation, and angiogenesis. Evidence from erythropoietin (EPO), a glycoprotein hormone that is secreted into the blood and binds to its cognate receptor on erythroid progenitor cells, thereby stimulating their survival and differentiation (29). Analysis of the sequences regulating hypoxia-induced EPO gene expression has revealed that hypoxia induces EPO expression and thereby causes upregulation of the paralog SSAT1 (29).

**Regulation of Target Genes**

HIF-1α binds to specific DNA sequences called hypoxia response elements (HREs), which are important regulators of angiogenesis and erythropoiesis. The structures and functions of HIF-1α-regulated target genes are indicated in FIGURE 2A. The regulation of HIF-1α target genes by HIF-1α can be either direct, as indicated by the arrow, or as a result of coordinated regulation by the hypoxia-inducible factor, HIF-1α, and other transcription factors.

**Angiogenesis**

Angiogenesis is the formation of new blood vessels from pre-existing vessels. Hypoxia-inducible factor-1α (HIF-1α) is a critical transcription factor in this process. It is activated in response to low oxygen levels and is involved in the regulation of genes that promote angiogenesis, such as vascular endothelial growth factor (VEGF) and its receptors.

**Regulation of HIF-1α Synthesis**

The synthesis of HIF-1α is regulated by multiple factors, including oxygen concentration, cellular energy status, and growth factor signaling. In cells under hypoxic conditions, HIF-1α expression is increased due to the inhibition of its degradation by the von Hippel-Lindau protein (VHL) complex. This leads to increased availability of HIF-1α, which binds to DNA and activates the transcription of genes involved in angiogenesis and erythropoiesis.

**Erythropoiesis**

Erythropoiesis is the production of red blood cells and is regulated by the hormone erythropoietin (EPO). EPO is produced by the kidneys in response to low oxygen levels and binds to its receptors on erythroid progenitor cells, leading to the activation of the HIF-1α pathway.

**Regulation of Target Genes**

HIF-1α regulates the expression of many genes involved in angiogenesis and erythropoiesis. These genes include VEGF, which promotes angiogenesis, and EPO, which acts on erythroid progenitor cells. HIF-1α also regulates the expression of genes involved in the production of hemoglobin, such as the β-globin gene.

**Angiogenesis**

Angiogenesis is a complex process that involves the formation of new blood vessels from pre-existing vessels. It is regulated by various factors, including growth factors, cytokines, and oxygen levels.
transcription led to the discovery of HIF-1 (72). Subsequently, HIF-1 has been shown to orchestrate erythropoiesis by coordinately regulating the expression of multiple genes encoding proteins responsible for the intestinal uptake, tissue recycling, and delivery of iron to the bone marrow for its use in the synthesis of hemoglobin (FIGURE 3A), including transferrin (66), transferrin receptor (48, 81), ceruloplasmin (53), and hepcidin (59). In addition, HIF-1 also activates transcription of the EPO receptor (51).

Erythropoiesis is impaired in Hif1a–/– (homozygous HIF-1α-null) embryos and the erythropoietic defects in HIF-1α-deficient erythroid colonies could not be corrected by cytokines, such as vascular endothelial growth factor (VEGF) or EPO, but were ameliorated by administration of Fe-salicylaldehyde isonicotinoylhydrazone, a compound that can deliver iron into cells independently of iron transport proteins, which was consistent with reduced levels of transferrin receptor in HIF-1α-deficient embryos and yolk sacs (93). In contrast, deficiency of HIF-2α (which, like HIF-1α, is O2 regulated, dimerizes with HIF-1β and activates target gene expression) has a major effect on EPO production in adult mice (23).

Angiogenesis

Erythropoiesis represents an adaptive response to systemic hypoxia. In contrast, angiogenesis represents a local tissue response to decreased oxygenation. As cells grow and proliferate, their consumption of O2 increases and HIF-1 activity is induced, either as a result of preemptive growth factor-mediated induction (FIGURE 2B) or as a result of tissue hypoxia (FIGURE 1A). HIF-1 then coordinately activates the transcription of multiple genes encoding angiogenic growth factors and cytokines (FIGURE 3B), including vascular endothelial growth factor (VEGF), stromal-derived factor 1 (SDF-1), placental growth factor (PLGF), angiopoietin 1 and 2, and platelet-derived growth factor B (5, 8, 18, 32, 76), which bind to cognate receptors on vascular endothelial and smooth muscle cells as well as on endothelial progenitor cells, mesenchymal stem cells, and other bone marrow-derived angiogenic cells (FIGURE 3B). In addition, HIF-1 regulates the expression of CXCL4 (79), which is the receptor for SDF-1, and VEGFR1 (22, 25).

Responses

Responses are restricted, and an illustration below. An illustration is shown below.
Glucose and energy metabolism

Individual cells must adapt to O2 deprivation by reprogramming their metabolism. The metabolic alterations that are induced by hypoxia are profound (Figure 3C). The most subtle adaptation identified thus far is a subunit switch that occurs in cytochrome c oxidase (COX; complex IV), in which the COX4-1 regulatory subunit is replaced by the COX4-2 isof orm as a result of HIF-1-mediated transcriptional activation of genes encoding COX4-2 and LON, a mitochondrial protease that is required for the hypoxia-induced degradation of COX4-1 (20). This subunit switch serves to optimize the efficiency with which COX transfers electrons to O2 under hypoxic conditions. Remarkably, the budding yeast Saccharomyces cerevisiae also switches COX subunits in response to hypoxia (40) but does so by a completely different molecular mechanism since yeast do not have a HIF-1 homolog. The similar regulation of COX activity in yeast and human cells indicates that the selection for O2-dependent homeostatic regulation of mitochondrial respiration is ancient and likely to be shared by all eukaryotic organisms (20).

A more drastic alteration is the shunting of pyruvate away from the mitochondria by the HIF-1-mediated activation of the PDK1 gene encoding pyruvate dehydroge nase (PDH) kinase 1 (45, 56), which phosphorylates the catalytic subunit of PDH, the enzyme that converts pyruvate into acetyl coenzyme A (AcCoA) for entry into the mitochondrial tricarboxylic acid cycle (Figure 3C), which generates reducing equivalents that are donated to the electron transport chain. The reduced delivery of substrate to the mitochondria for oxidative phosphorylation results in reduced ATP synthesis, which must be compensated for by increased glucose uptake via glucose transporters and increased conversion of glucose to lactate by the activity of glycolytic enzymes and lactate dehydrogenase A (Figure 3C), which are all encoded by HIF-1 target genes (27, 67, 69, 71).

Induction of PDK1 expression will inhibit the oxidative metabolism of AcCoA derived from glucose but will not affect the oxidative metabolism of AcCoA derived from fatty acids. The most draconian response to persistent hypoxia is the active destruction of mitochondria by selective mitochondrial autophagy (97). Remarkably, mice embryos thalam (MEFs) cultured at 1% O2 reduce their mitochondrial mass by ~75% within 48 h through autophagy that is initiated by the HIF-1-dependent expression of BNIP3, a mitochondrial protein that competes with Beclin1 for binding to Bcl2, thereby freeing Beclin1 to trigger autophagy (97).

The adaptive significance of these metabolic responses to hypoxia were revealed by the finding that HIF-1-deficient MEFs die when cultured under hypoxic conditions for 72 h due to dramatically increased ROS levels (35, 69). The cells can be rescued by overexpression of PDK1 or BNIP3, or by treatment with free-radical scavengers (35, 69). It has long been known that mitochondrial ROS production increases under hypoxic conditions (87). However, recent studies have demonstrated that acute hypoxia also leads to increased mitochondrial ROS production, which is required for the inhibition of HIF-1 by hypoxia (24). Exposure of wild-type (WT) MEFs to hypoxia for 48 h results in reduced ROS levels, in contrast to HIF1a+/– MEFs in which ROS levels are markedly increased (35, 97).

The following conclusions can be drawn regarding the metabolic adaptation to hypoxia. The increase in glycolysis and decrease in respiration that occur in response to hypoxia do not represent a passive effect of substrate (O2) deprivation but instead represent an active response of the cell to counteract the reduced efficiency of respiration under hypoxic conditions, which in the absence of adaptation results in the accumulation of toxic levels of ROS. These studies indicate that a major role of HIF-1 is to establish, at any O2 concentration, the optimal balance between glycolytic and oxidative metabolism that maximizes ATP production without increasing ROS levels. Finally, analysis of lung tissue from non-hypoxic Hif1a+/– mice, which are heterozygous for a HIF-1a-null allele and thus partially HIF-1a deficient, revealed an ~58% decrease in mitochondrial mass compared with WT littermates (97). This remarkable finding indicates that HIF-1 regulates mitochondrial metabolism even in the tissue exposed to the highest Po2, indicating that HIF-1 performs this critical function over the entire range of physiological Po2. Thus HIF-1 maintains the metabolic/redox homeostasis that is essential for metazoan cells to live with O2.

"This remarkable finding indicates that HIF-1 regulates mitochondrial metabolism even in the tissue exposed to the highest Po2..."
HIF-1-Mediated Pathological Responses to Hypoxia

Continuous hypoxia and pulmonary hypertension

The only organ to receive 100% of cardiac output is the lungs, which receive the blood that is pumped from the right ventricle. The pulmonary arterial circulation functions to load erythrocytes with O2. Blood is then returned to the left heart from which it is pumped through the systemic circulation to all tissues of the body. The O2 gradient in the systemic circulation dilates vessels in the lungs, where oxygenated blood is returned to the left heart from which it is pumped through the systemic circulation to all tissues of the body. The O2 gradient in the systemic circulation dilates vessels in the lungs, where oxygenated blood is returned to the left heart from which it is pumped through the systemic circulation to all tissues of the body.

HIF-1 mediates multiple pathogenic responses of pulmonary arterial smooth muscle cells (PASMCs) to hypoxia. HIF-1 inhibits the expression of the voltage-gated potassium channels Kv2.1 and Kv1.5 (90) and activates expression of the TRPC1 and TRPC6 store-operated calcium channels (89). Increased [K+]i and [Ca2+]i in PASMCs promote channel downregulation and vasoconstriction (89). HIF-1 also induces expression of the sodium-hydrogen exchanger NHE1, which increases intracellular pH and inhibits the expression of the sodium-potassium ATPase (88). Increased pH and [Ca2+]i trigger depolarization of PASMCs (74) and vesicle constriction (75). In addition, HIF-1 promotes the expression of endothelin-1, both in PASMCs and endothelial cells, leading to activation of endothelin receptors on PASMCs, which promotes further Kv1.5 channel downregulation and vasoconstriction (89).

HIF-1 also induces expression of the sodium-hydrogen exchanger NHE1, which increases intracellular pH (73). Increased [H+]i and [Ca2+]i in PASMCs promote cell proliferation. Finally, HIF-1 induces PASMC hypertrophy through mechanisms that have yet to be delineated (74). The combination of PASMC hypertrophy, constriction, and proliferation causes the reduction in the luminal diameter of pulmonary arterioles that underlies pulmonary hypertension (FIGURE 4A).

Mice heterozygous for a knockout allele at the locus encoding HIF-1α have increased basal ventilation and pulmonary hypertension that is observed in their WT littermates. Remarkably, individuals with Chuvash congenital polycythemia, who are homozygous for an arginine-to-tryptophan missense mutation at residue 200 in VHL that impairs its ability to bind to hydroxylated HIF-1α [1], have increased basal ventilation and pulmonary vascular tone, and augmented pulmonary vasconstrictive and cardiorespiratory responses to acute hypoxia (77). This phenotype is a striking complement to the impaired pulmonary vasconstrictive and cardiorespiratory responses to chronic hypoxia that are observed in Hif1a−/− mice (36, 94).

Chronic intermittent hypoxia and systemic hypertension

Whereas chronic continuous hypoxia induces pulmonary hypertension, chronic intermittent hypoxia (CIH) induces systemic hypertension. CIH occurs in individuals with obstructive sleep apnea (OSA), in which airway occlusion results in cessation of breathing leading to hypoxemia, which then arouses the individual to breathe. OSA may be a contributing factor in 30% of patients with essential hypertension (43). The carotid body is a small chemosensory organ located at the bifurcation of the internal and external carotid arteries that senses arterial P50. CIH induces signaling from the carotid body that activates the sym-
pametic nervous system, leading to increased catecholamine secretion, which increases arterial tone, leading to hypertension (43, 61). Exposure of HIF-1α−/− mice and their WT littermates to CHB for 10 days results in marked increases in systolic and diastolic blood pressures and a significant elevation in plasma norepinephrine concentration in the WT mice, where as their HIF-1α−/− littermates are unaffected (58). Remarkably, the carotid bodies of HIF-1α−/− mice, although structurally and histologically normal, do not respond to hypoxia, although they respond norm to CO and cyanide (36, 51).

CHB induces ROS production in rodents (62) and humans (16) and induces HIF-1α expression (58). Administration of the superoxide scavenger manganese tetra(1-methyl-4-phenyl-)porphyrin pentachloride to WT mice blocks CHB-induced ROS production (57), hypertension (39), and HIF-1α induction (58). Remarkably, in HIF-1α−/− mice, there is a complete loss of CHB-induced HIF-1α expression and ROS production (58). These results indicate that ROS production is required for HIF-1α induction and that HIF-1α induction is required for ROS production, suggesting a feed-forward mechanism in which ROS induces HIF-1α, which induces more ROS, leading to higher HIF-1α expression (FIGURE 4B).

In contrast to the physiological response to continuous hypoxia observed in MEFS described above, in which HIF-1α activity ameliorates increases in ROS levels, the pathological response to CHB is characterized by a HIF-1-dependent increase in ROS levels. OSA is a complication of obesity and, like other complications of hypoxia observed in MEFs described above, in which HIF-1 activity ameliorates increases in ROS levels. OSA is induced by a HIF-1-dependent increase in ROS levels required for HIF-1α induction (58). Remarkably, the carotid bodies of HIF-1α−/− mice, although structurally and histologically normal, do not respond to hypoxia, although they respond normally to CO and cyanide (36, 51).

Summary and Perspective

This review has summarized a small sample of the tremendous progress that has been made recently in understanding the molecular physiology of oxygen homeostasis and how it is dysregulated in various disease processes. The interested reader is encouraged to consult the many recent reviews that discuss other disease processes. The interested reader is encouraged to consult the many recent reviews that discuss other disease processes.
maintain oxygen homeostasis for life style, and so prevention of oxygen deprivation.
